

Candidate 3 evidence

How Acid Concentration Affects Reaction Rate.

Aim: To find out how increasing the acid concentration alters the rate of reaction.

Underlying chemistry:

Reaction rate measures how ~~quickly~~ fast a product takes to appear or for a reactant to be used up. It can measure how fast a reaction occurs. One of the factors affecting reaction rate is concentration. When the concentration of a solution gets increased, there ~~will~~ will be particles moving nearer to each other. This will mean more collisions are likely to happen, resulting in an increase of reaction rate. When the ~~concentration~~ reactants being used increase in concentration then the quicker the rate of reaction will occur.

Lower Concentration of Acid

Higher Concentration of Acid

When the acid being used is diluted then the hydrogen ions' concentration will ~~decrease~~ decreased resulting in the pH moving towards 7. Acidic solutions contain less hydroxide ions than hydrogen, whereas alkalis have less hydrogen ions and more hydroxide. Neutralisation can also take place when using acids. This is when acid reacts with a base to form salt and water. This also results in the pH moving closer to 7. Acids can be neutralised by metal carbonates. When they react together 3 products are formed, The formula used in this reaction is:-

Metal Carbonate + Acid \rightarrow Salt + Water + Carbon Dioxide

~~When~~ When testing the reaction rate given off when ~~only~~ changing the concentration of an acid the following method can be used:

(2)

Description of experiment:

Five chips of calcium carbonate were placed into a test tube with 15 cm³ of acid and a lid. A delivery hose attached the test tube to a trough of water containing a measuring cylinder placed upside down.

Experimental Data:

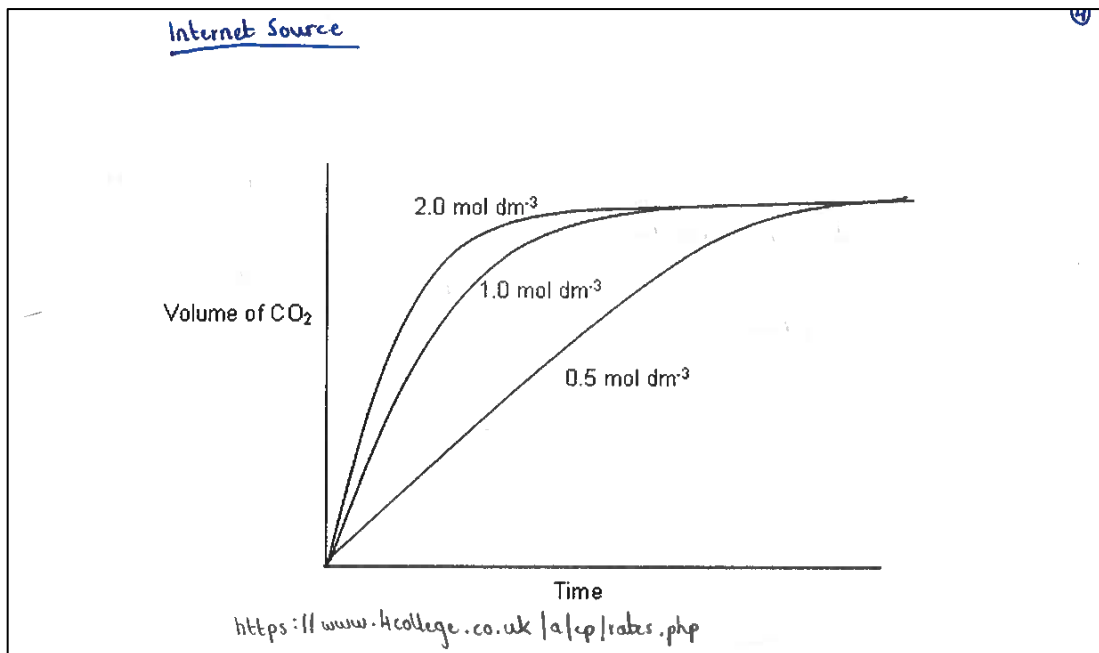

Acid Concentration (mol l ⁻¹)	Volume of Gas Given Off (cm ³)		Average Volume of Gas (cm ³)
	Test 1	Test 2	
0.5	27	26	26.5
1.0	53	56	54.5
1.5	75	70	72.5

$$\text{Rate of } 0.5 = \frac{\Delta \text{ quantity}}{\Delta \text{ time}} = \frac{26.5}{3} = 9 \text{ cm}^3 / \text{minute}$$

$$\text{Rate of } 1.0 = \frac{\Delta \text{ quantity}}{\Delta \text{ time}} = \frac{54.5}{3} = 18 \text{ cm}^3 / \text{minute}$$

$$\text{Rate of } 1.5 = \frac{\Delta \text{ quantity}}{\Delta \text{ time}} = \frac{72.5}{3} = 24 \text{ cm}^3 / \text{minute}$$

Analysis

Both the experimental data and the internet source were calculating how long it took for a reaction to occur whilst altering the concentration of a product. The internet changed the concentration by 0.5, 1.0 and 2.0 mol l⁻¹ and my experiments changed the concentration of the product by 0.5, 1.0 and 1.5 mol l⁻¹.

Conclusion

As we can see by this experiment, increasing the acid concentration of a product also increases the speed at which a reaction takes place. The higher the concentration became, ~~the more~~ a higher volume of gas was given off. ~~When the concentration changed from 0.5 to 1.0 and 2.0 mol l⁻¹, the volume of gas immediately increased by 100%, 200% and 300% respectively.~~

Evaluation

For the majority of the experiment, all results were reliable. We can see this because as the concentration ~~was~~ ^{were} increased, the volume of gas always went up by 50 cm³. To make the experiment reliable we ensured the exact number of acid went into the test tube and that there were no air bubbles in the measuring cylinder when calculating the volume of gas given off. Next time we can ensure the volume of gas is written down at the exact second, instead of reading the number up to ten seconds after the three minutes are over. This will make our results slightly more precise, and more accurate.
